Abstract
The present study was designed to determine the acute effect of sodium bicarbonate (NaHCO3) on the number of sprint repetitions during sprint high-intensity intermittent testing. In addition, blood biochemical (pH, HCO3-, and lactate) responses measured in three occasions were investigated. Thirteen male well-trained sprinters (24.65±3.44 yrs) performed two consecutive trials (7 days apart). Athletes were assigned randomly either to ingest a single dose of NaHCO3 (0.3 g/kg) 1 h prior to exercise or placebo using a double-blind crossover design. The intermittent sprint test consisted of 60 s treadmill sprints (90% of maximal work done) and 30-s recovery repeated intermittently until volitional exhaustion. Blood samples were collected from all athletes before exercise, after 1 h of dose intake, and after exercise in each trial. Paired sample t-testing showed that athletes complete significantly more sprint repetitions (p=0.036) during the intermittent sprint test with NaHCO3 (6.846±3.114) than with the placebo (5.538±3.872). Data also revealed no differences between trials in all blood responses at pre-exercise. After 1 h of dose consumption, however, blood pH and HCO3- were higher with NaHCO3 than with placebo (p<0.05), but no differences were noted in lactate between trials (p>0.05). After completion of the test, all blood responses were significantly higher with NaHCO3 than with placebo (p<0.05). In conclusion, intake of 0.3 g/kg of NaHCO3 1 h prior to treadmill sprint-intermittent performance increased sprint repetitions in well-trained sprinters, probably due to activated glycolysis caused by intracellular protons efflux into the blood.

EFFECT OF NaHCO3 ON SPRINT-INTERMITTENT EXERCISE
http://mjssm.me/?sekcija=article&artid=206

Introduction
High-intensity intermittent exercise results in a pronounced accumulation of glycolytic metabolites as a consequence of anaerobic energy delivery in the working muscles (da Silva et al., 2019; Danaher, Gerber, Wellard, & Stathis, 2014; Coso, Hamouti, Agudo-Jimenez, & Mora-Rodriguez, 2010; Sweeney, Wright, Brice, & Doberstein, 2010). As exercise progresses, the production of hydrogen cations (H+) increas-
es (Saunders et al., 2017) and the pH of the muscle declines (Hobson, Saunders, Ball, Harris, & Sale, 2012), which leads to acid-base imbalance. Increased acidity of the working muscles caused by H⁺ accumulation is a major cause of fatigue (Debold, Fitts, Sundberg, & Nosek, 2016; Fitts, 2016; Bishop, Edge, Davis, & Goodman, 2004) and can lead to performance impairments when exercise is performed at high intensities (de Salles Painelli et al., 2013; Tobias et al., 2013; Robergs, Hutchinson, Hendee, Madden, & Siegler, 2005). More specifically, muscle acidosis has been shown to impair energy transfer via the anaerobic system (da Silva et al., 2019), disrupt phosphoryl-creatine (PCr) resynthesis (Sahlin, Harris, & Hultman, 1975), and to inhibit the activity of key glycolytic enzymes, such as glycogen phosphorylase and phosphofructokinase (da Silva et al., 2019). Subsequently, the ability of the muscles to cope with high-energy demands decreases (Gladden, 2004).

Although a great portion of the contraction-induced H⁺ is rapidly transported out of the working myocytes to blood and buffered by bicarbonate (HCO³⁻) (de Salles Painelli et al., 2013; Requena, Zabala, Padial, & Feriche, 2005), blood acidosis could also contribute to fatigue indirectly during high-intensity exercise (Price, Moss, & Prance, 2003; Hobson et al., 2012). In this context, nutritional supplements have been shown to attenuate acidosis and delay fatigue; sodium bicarbonate (NaHCO₃) is one of them. NaHCO₃ is the most frequently alkalotic agent used by athletes who rely on glycogenolysis to delay fatigue (da Silva et al., 2019; Saunders et al. 2017) and reduce ratings of perceived exertion (RPE) (Carr, Slater, Gore, Dawson, & Burke, 2011). NaHCO₃ can increase the extracellular buffering capacity by increasing blood HCO₃⁻ concentration (de Salles Painelli et al., 2013; Oliveira et al., 2017) in which it enhances H⁺ efflux from the working muscles to the blood (da Silva et al., 2019; de Salles Painelli et al., 2013) where they are neutralized (Bishop et al., 2004).

Several investigations have shown that increased circulation-buffering capacity, achieved either by acute (single dose) or chronic (supplementation) NaHCO₃ intake, improves performance and capacity at high intensities (Carr et al., 2011; Requena et al., 2005; Tobias et al., 2013; Lancha Junior, de Salles Painelli, Saunders, & Artioli, 2015). This indicates that NaHCO₃ has been reported to be beneficial in events with high-intensity exercise lasting from approximately 1 to 5 minutes (Carr et al., 2011; Saunders et al., 2017; Tobias et al., 2013), with utilized dose ranging from 0.1 to 0.5 g/kg body mass (McNaughton, Backx, Palmer, & Strange, 1999). The mechanism proposed to be reasonable for the effect of NaHCO₃ involves increased activation of the glycolytic and the adenosine triphosphate (ATP)-PCr systems (Deb, Gough, Sparks, & McNaughton, 2018), although elevation in blood lactate has been demonstrated following NaHCO₃ intake (Artioli et al., 2007).

Studies using repeated sprint bouts of high-intensity exercise have observed performance improvement (Price et al., 2003; Bishop et al., 2004; Tobias et al., 2013; Deb et al., 2018), but others failed to report beneficial effects (de Araujo Dias et al., 2015; de Salles Painelli et al., 2013; da Silva et al., 2019). Beside of discrepancies associated with the beneficial effect of NaHCO₃, high volume and intensity exercise could induce acid-base disturbances (Carr et al., 2013). Additionally, although NaHCO₃ has been studied for years, most investigations have been conducted using cycling ergometer tests. However, the effect of NaHCO₃ intake on blood responses during repeated sprint-intermittent testing on a treadmill remains poorly investigated, and its effect on exercise capacity has yet to be demonstrated. Therefore, this study aimed to determine the number of sprint repetitions during treadmill high-intensity intermittent exercise protocol until volitional exhaustion. A secondary aim of this study was to investigate the concentrations of blood pH, HCO₃⁻, and lactate in response to exercise. We hypothesized that extracellular buffering capacity by ingesting acute NaHCO₃ might attenuate blood acidity and improve performance.

Methods
Participants
Thirteen male well-trained sprinting athletes (see Table 1 for participants demographic data) volunteered to participate in the present study, following being informed about the potential risks and benefits involved in participation. All athletes had been involved in a sprinting training at the Jordan Military Sports Federation for a minimum of five years. Other inclusion criteria for participation were the following: long male athletes; age ranged 20-30 years old; no previous injuries for at least four months, and not consuming NaHCO₃ or any ergogenic aids seven days prior to participation. This study was approved in advance by the local scientific research committee of Yarmouk University (protocol. 11-2019 M.A). Each participant voluntarily provided written informed consent before participation.

Experimental design
Athletes performed two experimental trials in which they ingested a single dose of NaHCO₃ (Premium sodium bicarbonate powder, VITADIRECT, USA) or maltodextrin (placebo). The trials were randomized and separated by one week to complete recovery, with both trials performed at the same time of the day (07:45 AM) to ensure that the findings were not affected by circadian rhythm. NaHCO₃ and placebo were coded before data collection. The doses were administered in a crossover design, with the double-blind provision of NaHCO₃ and placebo, as neither examiners nor athletes were aware of the experimental treatment. Each trial consisted of 1) intake...
of NaHCO₃ or placebo in the laboratory one hour prior to exercise, 2) a standardized 10-min warm-up (treadmill jogging with a speed of 7-8 km/h, joint mobilization, and stretching), and 3) repeated intermittent sprint test on a treadmill. Athletes were instructed to refrain from drinking water during the trial. The exercise protocol in both trials was performed in a cool environment (20-22°C) and 42-45% relative humidity.

**Experimental procedure**

Each athlete visited the laboratory on four different occasions. Athletes’ characteristics and vital factors were measured on the first visit. On the second visit, each athlete engaged in a warm-up to prepare themselves for running on a treadmill (Technogym Excite + RUN 1000-19” LED Touchscreen, Italy). They engaged in running three bouts with different speeds that ranged from low to moderate (7-13 km/h) for 10 min. On the next day (third visit), each athlete was familiarized with running on the treadmill for 15 min. After a 5 min rest, the athletes underwent a graded exercise test to determine \( V_{O_{2} max} \), in which exercise intensity is progressively increased while measuring ventilation and oxygen and carbon dioxide concentration of the inhaled and exhaled air. \( V_{O_{2} max} \) is reached when oxygen consumption remains at a steady state despite an increase in workload (see Price et al., 2003). This regimen was done to measure the athletes’ greater speed (intensity) associated with \( V_{O_{2} max} \) while performing in each trial for a 60 s sprint. Determination of \( V_{O_{2} max} \) was to know the efficacy of cardiopulmonary status and to indicate a preparedness of athletes’ ability to perform the intermittent sprint test effectively. The results of athletes’ \( V_{O_{2} max} \) and greater treadmill speed were 59.36±3.61 ml/kg/min; 17.05±1.71 km/h, respectively.

On the fourth visit, we repeated the regimen for each athlete to confirm the intensity (speed) of the exercise. Test-retest showed no difference in \( V_{O_{2} max} \) (t=2.14, p=0.32) and maximal speed (t=0.65, p=0.73). Athletes then asked to perform the intermittent sprint test at a speed of 7-8 km/h, joint mobilization, and stretching, and after the finish of the test in comparison to the pre-exercise level (t=2.401, p=0.032). Statistical analysis was conducted using SPSS version 18.0 and Microsoft Excel. Significance was set at \( P<0.05 \) for all analyses. Statistical analysis was conducted using SPSS version 18.0 and Microsoft Excel.

**Results**

Data revealed that the number of sprint repetitions during the intermittent sprint test were significantly greater with NaHCO₃ (6.846±3.114) than with the placebo (5.538±3.872) (t=4.113, p=0.036). Table 2 illustrates the results of blood biochemical responses to the NaHCO₃ at three time points: 1) pre-exercise, 2) 1 h after dose intake, and 3) post-exercise. The analysed data showed statistical differences in all blood responses. Post hoc using Bonferroni with adjusted means revealed that both blood pH and HCO₃⁻ were significantly higher after 1 h of NaHCO₃ intake compared to pre- (F=4.201, p=0.027; F=3.817, p=0.030 for pH and HCO₃⁻, respectively) and post-exercise (F=3.522, p=0.034; F=2.961, p=0.041 for pH and HCO₃⁻, respectively), whereas blood lactate level was elevated after the finish of the test in comparison to the pre-exercise level (F=6.012, p=0.003) and 1 h post-dose (F = 8.976, p = 0.001), with no differences between pre-exercise and 1 h post-dose (F=0.351, p=0.468).

Table 3 illustrates the results of blood biochemical responses to the placebo at the same three time points. Data showed differences in all blood responses. Post hoc using Bonferroni with...
adjusted means revealed that both blood pH and HCO₃⁻ were higher after 1 h of placebo intake compared to pre- (F=5.101, p=0.003; F=2.676, p=0.480 for pH and HCO₃⁻, respectively) and post-exercise (F=2.676, p=0.048 for pH and HCO₃⁻, respectively), with no differences between pre-exercise and 1 h post-dose (F=0.859, p=0.337; F=0.343, p=0.401). After the finish of the test, the blood lactate level was increased over the post-exercise level than pre-exercise (F=5.396, p=0.004) and 1 h post-dose (F=5.091, p=0.003), with no differences between pre-exercise and 1 h post-dose (F=0.286, p=0.573).

Discussion

The primary finding of the present study was that NaHCO₃ ingestion was an effective strategy to complete significantly more sprint repetitions when compared to ingestion of the placebo. This result could be explained by the excessive blood HCO₃⁻ concentration due to NaHCO₃ consumed before the beginning of the trial, in which it enhances intracellular H⁺ efflux. It has been documented that NaHCO₃ administration can attenuate roughly 62% of the H⁺ diffused from working muscle cells to the blood during highly intensive exercise (Carr, Webster, Boyed, Hudson, & Scheett, 2013; Medbo & Tabata, 1993). Additionally, NaHCO₃ can also contribute to delay the onset of fatigue by maintaining energy-producing capability (Carr et al., 2013; Requena et al., 2005) and elicit a calcium release from the sarcoplasmic reticulum (Requena et al., 2005), potentiating the actomyosin coupling system, and thereby increasing muscle capacity.

The result of our study agreed with the finding of Deb et al. (2018), who showed that exercise tolerance during an intermittent exercise test (60-s work in high-intensity to exhaustion, separated by 30-s recovery interval) was significantly greater after 0.3 g/kg body mass of NaHCO₃ (845.3±242.4 s) compared to placebo trial (734.3±175.7 s). However, their protocol was carried out on a cycle ergometer, and the participants were recreationally active male individuals. Another study conducted by Price et al. (2003) also demonstrated that the intake of 0.3 g/kg of NaHCO₃ 1 h prior to exercise increased peak power (11.5 ± 5%) expressed relative to a trial of sprint testing compared to sodium chloride (NaCl, 1.8±9.5%). In the same study, participants were nonathletes and completed an incremental cycle ergometer test which consisted of two 30-min intervals (repeated 3-min blocks; 90 s at 40% VO₂ max, 60 s at 60% VO₂ max, 14-s maximal sprint, 16-s rest). Tobias et al. (2013) reported enhanced high-intensity intermittent upper-body performance (4 30-s Wingate test, separated by 3 min) following chronic beta-alanine (BA) supplementation (6.4 g/day for 4 weeks) combined with 500 mg/kg of NaHCO₃ ingested within seven days compared to a placebo in well-trained athletes. The total work done in that study was increased by 8% in the mode
of NaHCO₃ supplementation, which differed from our protocol. However, it has been suggested that chronic NaHCO₃ can elicit muscular capacity similarly with an acute intake (Artioli et al., 2007).

Our findings were contrary to further studies. Recently, da Silva et al. (2019) showed that a combination of BA supplementation (6.4 g/day for 28 days) and acute NaHCO₃ (0.3 g/kg) 60 min prior to cycling time-trial (60-s bouts at 110% of maximal power output, separated by 60-s rest) did not improve performance compared to each one alone and placebo in male cyclists. However, they suggested that NaHCO₃ increased the estimated glycolytic ATP-PCr systems. de Salles Painelli et al. (2013) reported that 0.3 g/kg of NaHCO₃ intake following BA supplementation (3.2-6.4 g/day for 4 weeks) had no ergogenic effect in 100- and 200-m swimming performance in swimmers. A limitation of that study was the lack of blood HCO₃⁻ measurement, so they failed to suggest an explanation for non-significant performance improvement. de Araujo Dias et al. (2015) observed that the ingestion of 0.3 g/kg of NaHCO₃ did not affect graded high-intensity cycling capacity test which initiated at 100 W and increased by 6 W every 15 s until volitional exhaustion compared to placebo. The explanation of their finding was attributed to a variability of monocarboxylate (MCT) transporter protein activity after NaHCO₃ intake and to H⁺ efflux ratio from myocytes into blood. However, participants recruited in that study were recreationally active individuals. In addition, conflicting findings have been observed when the duration of an exercise lasting less than 2 min (Requena et al., 2005). Danaher et al. (2014) showed no differences in repeated sprint ability (RSA) test (5 repeats of 6 s maximal effort cycling bouts, separated by 24 s rest) between NaHCO₃ (300 mg/kg), BA (4.8-6.4 g/day for 4 weeks) and placebo trials. However, time-to-exhaustion during cycling capacity test performed following RSA was increased 16% with a combination of NaHCO₃+BA. The lack of ergogenic effect of NaHCO₃ intake upon performance in previous studies might be associated with the type of exercise protocol, the duration of exercise, the small number of the sample, the intensity of exercise, and the environmental temperatures.

Our results showed that blood pH and HCO₃⁻ were significantly higher after the finish of the test in the NaHCO₃ trial than that of the placebo trial, which might indicate the effective buffering capacity of the extracellular median due to NaHCO₃ intake. Increased extracellular pH and raised HCO₃⁻ due to NaHCO₃ consume might raise the H⁺ and lactate efflux from working muscles (Requena et al., 2005) by increasing the activity of the lactate/H⁺ cotransporter. This mechanism delays the drop in pH (Mars et al., 2002), delays the onset of fatigue (Hobson, et al., 2003), and leads to higher contractile force (McNaughton et al., 1999) by sustained muscle glycolytic ATP production (McKenzie, Couts, Stirling, Hoeben, & Kubara, 1986; Kemp & Foe, 1983). In this context, however, increased activation of glycolytic ATP-PCr systems induce high lactate levels (da Silva et al., 2019). Increased post-exercise lactate has been reported after NaHCO₃ intake (da Silva et al., 2019; Bishop et al., 2004), which might explain the elevated blood lactate after the finish of the test in the NaHCO₃ trial compared to the placebo in the present study. Additionally, the greater sprints repetitions as a result of NaHCO₃ consume was also contribut-ed to elevation in blood lactate levels. In a study conducted by Deb et al. (2018), blood HCO₃⁻ was significantly higher in experimental trial after intermittent testing (16.0±2.0 mmol/L) compared to 13.0±3.0 mmol/L in a placebo trial, and blood pH was decreased from 7.47 (pre-test) to 7.31 (post-test) in NaHCO₃ trial compared to placebo (7.39; 7.20, respectively). In the same study, however, post-test blood lactate was signifi-cantly elevated in NaHCO₃ trial (17.9±5.9 mmol/L) compared to a placebo (13.9±4.3 mmol/L). da Silva et al. (2019) found that blood lactate (15.7 mmol/L), pH (7.30), and HCO₃⁻ (22.1 mmol/L) were significantly changed after exercise compared to placebo (12.0 mmol/L; 7.25; 19.5 mmol/L, respectively).

Painelli et al. (2013) reported that 0.3 g/kg of NaHCO₃ intake significantly elevated in NaHCO₃ trial (17.9±5.9 mmol/L) compared to a placebo (13.9±4.3 mmol/L). da Silva et al. (2019) found that blood lactate (15.7 mmol/L), pH (7.30), and HCO₃⁻ (22.1 mmol/L) were significantly changed after exercise compared to placebo (12.0 mmol/L; 7.25; 19.5 mmol/L, respectively). Hobson et al. (2013) showed that chronic BA (6.4 g/day for 4 weeks) followed by acute NaHCO₃ (0.2 g/kg) were likely to be beneficial to 2.000-m rowing performance, with increased post-exercise blood pH, HCO₃⁻ and lactate compared to placebo group in rowers.

Conclusion

It can be concluded from the present data that acute (single dose) sodium bicarbonate can attenuate acidosis during high-intensity intermittent exercise and improve performance following intake 0.3 g/kg orally in well-trained sprinters, which indicates that sodium bicarbonate may act as a physicochemical buffer in the body and may represent, in part, an explanation for the ergogenic effect in sprint-intermittent exercise. Additionally, these data confirm that post-exercise blood lactate increases after the consumption of sodium bicarbonate.
